that soil chemical denudation rates increase proportionally with erosion rates. These high weathering rates support the view that mountains play a key role in global-scale chemical weathering climate through links among rock uplift, relief generation, erosion, silicate weathering, and CO2 cycling (1–4). The existence of these late tectonics has long been thought to influence climate through links among rock uplift, relief generation, erosion, silicate weathering, and CO2 cycling (1, 2). Determining the form of the functional relationship between hillslope erosion and weathering rates is critical for understanding how or if mountains influence global weathering budgets and climate particularly relevant to nanoscale substrates, where the curvature is appreciable on molecular length scales. For example, solid domains consisting of narrow stripes radiating outward from a circular core have been observed in diverse systems, such as phases on lipid vesicles (17) and metal coatings on nanoparticles (18). Our analysis suggests that the width of the stripes and the core size should be determined by the interplay among curvature, elasticity, and bulk energy. A similar interplay may affect the assembly pathways of viral capsids. Recent in vitro experiments (26) show that capsids can assemble following a two-step mechanism analogous to our crystallization process: The capsid proteins first attach to a substrate (an RNA molecule) and then bind together into an ordered shell. The intermediate states of this process—long a subject of speculation (19)‐might contain voids that, like those in our curved crystals, help the capsids avoid excess elastic stress (27, 28).

Similar rules may govern other crystallization and packing problems where global geometry is incompatible with local lattice packing. For example, crystallization of tetrahedra is frustrated in flat (Euclidean) 3D space (6). However, logs and helices of tetrahedra are prevalent in first-order phase transitions of tetrahedra from ordered to disordered quasicrystalline phases (7). The existence of these structures, which were first described by Bernal (29), may reflect a similar physical principle, in which growth along one dimension allows a crystal to escape the restrictions of geometrical frustration.

Rapid Soil Production and Weathering in the Southern Alps, New Zealand
Isaac J. Larsen,1,* Peter C. Almond,2 Andre Eger,2† John O. Stone,1 David R. Montgomery,1,‡ Brendon Malcolm1

Evaluating conflicting theories about the influence of mountains on carbon dioxide cycling and climate requires understanding weathering fluxes from tectonically uplifting landscapes. The lack of soil production and weathering rate measurements in Earth’s most rapidly uplifting mountains has made it difficult to determine whether weathering rates increase or decline in response to rapid erosion. Beryllium-10 concentrations in soils from the western Southern Alps, New Zealand, demonstrate that soil is produced from bedrock more rapidly than previously recognized, at rates up to 2.5 millimeters per year. Weathering intensity data further indicate that soil chemical denudation rates increase proportionally with erosion rates. These high weathering rates support the view that mountains play a key role in global-scale chemical weathering and thus have potentially important implications for the global carbon cycle.

Fig. 4. (A) Measurements of domain length l (black) and width w (gray) as a function of time for a droplet with R = 18 μm (18). Images of domain morphologies at various times are shown at top (see also movie S1). The transition from isotropic to anisotropic growth occurs at about 100 min. (B) Distribution of l and w, both normalized to the radius of curvature R, for curved crystals. The dashed line marks the isotropic regime where w = l. w/R is roughly constant, in agreement with the model.

Chemical depletion fractions increase with soil thickness (Fig. 2C) and decline with increasing soil production rates (Fig. 2D), which is consistent with declining soil residence times that models predict at high denudation rates (3–5) and measurements from the San Gabriel Mountains (17). However, the high P values preclude concluding that the regression slopes are significantly different from zero. Thus, weathering may be supply-limited at the very high denudation rates we observe. Regardless of whether the chemical denudation data conform to supply- or kinetically limited weathering, the chemical denudation rates inferred from the Zr and \(^{10}\)Be data increase linearly with physical erosion rates (Fig. 2E). Comparison of our soil chemical denudation rates against a compilation of worldwide data indicates that soil chemical denudation rates in the western Southern Alps are the highest values yet determined, and the power-law scaling exponent of \(\sim 1.0\) indicates that chemical denudation rates increase linearly as erosion rates increase by nearly three orders of magnitude (Fig. 3A).

The relationship between soil chemical denudation and physical denudation rates observed in the western Southern Alps is consistent with data from more slowly eroding landscapes (18) and extends the range of soil production rates over which weathering and denudation rates increase in proportion to one another to much higher values than previously recognized. If the relationship becomes nonlinear or reverses to an inverse correlation, as predicted by several models (3–5), it does so at rates higher than we observe in the western Southern Alps. Hence, our findings do not support the view that mountains are inefficient sites for weathering because of “speed limits” to soil production and chemical denudation (19); values from the western Southern Alps break the proposed speed limits for both soil production and soil weathering.

\(^{10}\)Be concentrations in sediment indicate that total denudation rates for watersheds in the western Southern Alps range from 1 to 9 mm year\(^{-1}\) (Fig. 1). Small catchments that drain areas within 1 to 2 km of the Alpine Fault have the lowest denudation rates of 1 to 2 mm year\(^{-1}\). Larger catchments and subcatchments that drain areas farther to the east of the Alpine Fault denude at rates of 4 to 12 mm year\(^{-1}\). The spatial pattern of decreasing watershed-scale denudation toward the Alpine Fault is consistent with crustal velocity fields predicted by simple shear deformation (20) and vertical deformation measured by global positioning systems (21).

The maximum soil production rate that we measured in the western Southern Alps equals or exceeds denudation rates for the more slowly eroding watersheds. However, for a given catchment, soil production rates are a fraction of the catchment-averaged denudation rates. Hillslopes below the tree line in the western Southern Alps have very little bedrock exposure, even though soil production rates are lower than catchment-averaged denudation rates. The landscape maintains a soil mantle because the return interval for landslides, which must account for the balance of catchment-averaged denudation not attributable to soil production (10), is long enough at any point on the landscape that soils develop between failures (22). The soil-mantled hillslopes and high soil production rates in the western Southern Alps indicate that, contrary to previous suggestions (23), hillslopes are not necessarily stripped of soil at high uplift rates. Although strong evidence for a transition from soil-mantled to bedrock hillslopes exists for the San Gabriel Mountains (22, 24), mean annual precipitation in the San Gabriel Mountains is an order of magnitude lower than in the western Southern Alps. We suspect that the emergence of bare bedrock hillslopes in tectonically active landscapes is modulated in large part by climate, with soil production able to proceed at higher rates in wetter, and thus more vegetated, regions, such as our study area.

The high mean annual precipitation promotes rapid leaching (14) and supports high annual vegetation productivity (25), which we suggest, along with pervasively fractured bedrock, contribute to the high soil production rates that we observe. The primarily biotic driver of soil production is vegetation, because burrowing mammals, which contribute to soil production in other landscapes (16), are not endemic to New Zealand. Coarse and fine roots readily penetrate bedrock by exploiting foliation planes and fractures generated by tectonics (15) and erosional unloading (fig. S1). Root expansion in fractures, especially...
foliation planes within a few cm of the soil-bedrock interface, likely plays a key role in converting rock to soil, both by physically breaking rock and by enhancing chemical weathering through organic acid production and increased subsurface CO₂ concentrations.

The high soil production rates in the western Southern Alps are consistent with estimated soil residence times of only a few centuries (14) and rapid weathering and leaching (26) documented at other sites on the South Island’s west coast. Soil production rates also increase with watershed-scale denudation rates, as observed in more slowly eroding landscapes (22). Soil production rates have not been measured in other mountains undergoing uplift rates comparable to those in the western Southern Alps. However, in the Taiwan orogen, hillslopes are soil-mantled even though landslides—which primarily mobilize soil—erode the landscape at rates >2 mm year⁻¹ (27). Similarly, hillslopes in the Tsangpo Gorge of the eastern Himalaya are soil mantled, despite erosion rates >4 mm year⁻¹ (28), suggesting that soil production rates in other landscapes are also sufficiently rapid that hillslopes are not stripped to bedrock, despite high rates of rock uplift and erosion.

Global river solute and sediment yield data (29) demonstrate that catchment-averaged chemical denudation rates span a similar range of values as global soil chemical denudation rates, although the power-law scaling exponent less than unity differs from the soils data (Fig. 3B). River solute data indicate that catchment-scale chemical denudation rates in the western Southern Alps are of the same magnitude as soil chemical denudation rates. However, chemical denudation accounts for <5% of catchment-scale denudation (12, 30). Similarly, the mean soil chemical denudation rates that we determined are 1 to 7% of the¹⁰Be-based total denudation rates determined for each watersheds, whereas mean chemical denudation is 16 to 32% of the soil production rate at each of the ridgetop sites. The differing ratio of chemical to total denudation rates observed for soils versus catchments is likely due to a high proportion of unweathered rock in the debris delivered to rivers by landslides. A more detailed geochemical budget is required to assess weathering fluxes from deep bedrock (6) and landslide-affected terrain (31), but if soil dynamics at the sites we sampled are at least broadly representative of those occurring throughout the landscape, our results suggest that soil weathering may be an important contributor to the high weathering flux in the western Southern Alps (12, 30, 32).

The high denudation rates in the western Southern Alps are consistent with global fluxes determined using river load data, which demonstrate that young, wet mountains make up only 14% of the ocean-draining land area but account for 62% of sediment, 38% of total dissolved solid, and 60% of dissolved silica delivered to Earth’s oceans (29). Hillslopes in rapidly uplifting mountains appear to bypass the hypothesized weathering speed limit because high rates of orographic precipitation support ecosystems that physically break up rock and promote weathering and leaching, allowing rapid soil production to contribute to the high orogen-scale weathering fluxes.

Fig. 2. Soil production rates, chemical depletion data, and chemical versus physical denudation rates. (A) Soil production rate versus soil thickness for the western Southern Alps. Soil production rates decline exponentially with increasing soil thickness at the Gunn Ridge and Rapid Creek sites, and the respective exponential regression fits are \( y = 1.71(0.71–0.50)e^{-0.056(0.012)x} \), \( R^2 = 0.82 \), \( P = 0.005 \) and \( y = 3.18(1.33–0.94)e^{-0.054(0.035)x} \), \( R^2 = 0.83 \), \( P = 0.03 \). (B) Western Southern Alps soil production rates and soil production functions plotted with a worldwide compilation of soil production functions; see supplementary materials for data sources. (C) Chemical depletion fraction (CDF) versus soil thickness for the western Southern Alps. CDF values increase with soil thickness as \( y = 0.0073(0.0040)x – 0.052(0.12) \), \( R^2 = 0.39 \), \( P = 0.13 \) for Gunn Ridge and \( y = 0.0077(0.0023)x + 0.18(0.057) \), \( R^2 = 0.79 \), \( P = 0.04 \) for Rapid Creek. (D) CDF versus soil production rates for the western Southern Alps. CDF values decline as soil production rates increase, as \( y = –0.11(0.070)\ln(x) + 0.036(0.081) \), \( R^2 = 0.35 \), \( P = 0.16 \) for Gunn Ridge and \( y = –0.10(0.062)\ln(x) + 0.35(0.039) \), \( R^2 = 0.48 \), \( P = 0.20 \) for Rapid Creek. (E) Chemical denudation rate versus physical denudation rate for the western Southern Alps. Chemical denudation rates increase linearly as physical denudation rates increase. The linear reduced major axis (RMA) regression fit shown by the line is \( y = 0.49(0.036)x – 0.052(0.017) \), \( R^2 = 0.89 \), \( P < 0.001 \). Error bars and parentheses indicate ±1 SE; \( P \) values based on \( t \) statistics.

Fig. 3. Chemical versus physical denudation rate for worldwide soil and river data. (A) The RMA power-law fit to the soil mass flux data is $y = 0.37(\pm0.12/–0.09)x^{1.025(0.059)}$, $R^2 = 0.38$, $P < 0.001$, indicating that chemical denudation increases linearly as physical denudation rates increase by nearly three orders of magnitude. (B) The RMA power-law fit to the river mass flux data (29) is $y = 2.66(0.39–0.35)x^{0.63(0.028)}$, $R^2 = 0.41$, $P < 0.001$. The hypothesized global weathering speed limit (19) (horizontal dashed line) is shown for reference. Also shown are river flux–based denudation data from the western Southern Alps (11, 12, 30); note that river and soil chemical denudation rates in the western Southern Alps are of similar magnitude. The upper and right axes with length units are related to the mass flux axes by a density of 2.65 g cm$^{-3}$ and thus are approximate and for reference only, because rock density varies among the samples. See supplementary materials for data sources.
